An Evidence-based Approach to the Conservative Management of Insertional Achilles Tendinopathy

Introduction

The Achilles tendon is the strongest and largest tendon in the body, but it is also the most commonly ruptured tendon. The overall incidence of Achilles tendon rupture is on the rise recently because of the aging of the population, growing prevalence of obesity, and increased participation in sports. For all the research that has been done relating to the Achilles and insertional Achilles tendinopathy (IAT), there are still many unanswered questions. Why is the tendon aligned in a spiral or helix? Why are there three insertion points of the Achilles into the calcaneus? Why is the gastroc/soleus complex firing eccentrically at initial contact while the ankle is plantarflexing? We know it’s an ankle plantarflexor, but what is the eccentric function of the Triceps Surae?

Why are outcomes from conservative management so disappointing? There is a need to drive the development of novel conservative care treatments and to refine existing methods designed to prevent the progression and/or reoccurrence of IAT. The goal of this article is to report data and evidence for developing answers to these questions.

Anatomy (Figure 1) The Achilles tendon is an incredibly strong structure whose elastic spring-like properties allow it to deliver explosive propulsion during ambulation up to 3500 N before rupture. The collagen fibers of the tendon are highly organized structures that demonstrate high strength in the direction of fiber alignment. It originates from the aponeuroses of the gastrocnemius, soleus, and plantaris muscles, while the soleus inserts medially and the lateral gastrocnemius inserts laterally into the calcaneus. The inferior facet, or insertion of the superficial component of the Achilles tendon, is composed of the medial gastrocnemius muscle.

The tendon progressively twists as it descends from its origin, causing the gastrocnemius fibers to insert posterolaterally on the calcaneus while the fibers of the soleus insert anteromedially. The sub-tendons of the Achilles tendon spiral and intertwine as they move laterally and distally towards their insertion sites. Mahan notes that the twisting allows for
greater biomechanical strength. In this literature search there weren’t any other references for any other tendon having a spiral for that purpose.

**Risk factors**

There are multiple mechanisms potentially involved as risk factors in a person acquiring IAT. IAT has a bimodal age distribution with the first peak in patients between 25 years and 40 years of age and the second peak in those over 60 years. Several authors note intrinsic factors including anatomic factors, age, sex, metabolic dysfunction, foot cavity, dysmetria, muscle weakness, imbalance, gastrocnemius dysfunction, anatomical variation of the plantaris muscle, tendon vascularization, torsion of the Achilles tendons, slippage of the fascicle, and lateral instability of the ankle. Extrinsic factors noted by the same authors include mechanical overload, constant effort, inadequate equipment, obesity, medications (corticosteroids, anabolic steroids, fluoroquinolones,) improper footwear, insufficient warming or stretching, hard training surfaces, and direct trauma, among others. There is a 3.5 to 1 male to female ratio.

Multiple authors reported weakness or dysfunction of the gastrocnemius as a causative factor leading to IAT. The weakness can occur as a result of excessive forces crossing a presumed normal healthy Achilles in the elite athlete population, or normal forces crossing an impaired Achilles in the older diabetic obese population. In either case, the Achilles wasn’t strong enough to manage the stress it was being asked to handle. There is only one reference to weak hip abductors being a contributing factor in acquiring IAT. Research in this area might help explain the spiral configuration of the Achilles.

**Incidence**

There is general agreement that degenerative disorders of the Achilles are common, affecting up to 18% of the adult population with an annual incidence of 6% to 18% in the United States. Achilles tendinopathy is the most prevalent lower extremity tendinopathy, with a 5.9% frequency in sedentary people and around a 50% frequency in elite endurance athletes. In the elite track and field population, middle-distance runners have the highest reported prevalence of 83%. Of all the Achilles tendinopathies, IAT comprises 20% to 25% of the injuries.

**Mechanism of injury**

There is wide agreement in the literature that IAT is commonly driven by an overuse injury with symptoms that are exacerbated by mechanical loading and compounded by chronic failure of the healing response. Kau postulated that after repetitive mechanical loads and/or when the load exceeds the strength of the tendon, the tendon can become progressively micro- and macroscopically damaged. Put most succinctly, the most common cause of IAT in athletes is excessive loading. Adding fuel to the fire, the measurement of reduced DF range of motion is not the issue, and that the real issue may rest with (inadequate) plantarflexor muscle strength (torque/power).

The spiral design of the Achilles plays into the fact that there are three insertion points of the Achilles into the calcaneus. Because of this, different regions of the tendon are subjected to different types of
The superficial side of the tendon is subjected to greater axial tensile strain on both the gastrocnemius and soleus muscles. In contrast, the deep side of the tendon originating from the soleus is subjected to greater transverse compressive strain.

Traditional conservative management success rates

There seems to be universal agreement with Dilger and others that non-operative care is a first line approach for treating IAT, but not everyone is enthusiastic about that approach. Bah reports that IAT is a painful and debilitating condition that responds poorly to non-surgical interventions. Others report that nonoperative treatment will fail in approximately 50% of these cases. Conservative management is reported to be unsuccessful in 24% to 45.5% of AT patients, and that surgery is generally recommended after 6 months of conservative management. Data from Wirth are a little more optimistic with conservative management providing favorable outcomes for 71% of the cases, with as many as 25% of patients going on to surgery.

Conservative management protocols

Several authors report that rest and immobilization are used, especially in the acute phase. A number of studies recommend either a pneumatic walking boot or plastic molded AFO (MAFO) to relieve stress, ensure rest and prevent excessive ankle dorsiflexion. Park recommends 6 to 8 weeks of immobilization, but then adds the caveat that prolonged immobilization should be avoided. Other conservative measures mentioned by the same authors include ice, rest, heel lifts, stretching, activity modification and nonsteroidal anti-inflammatory drugs (NSAIDs).

Conservative management has been associated with a higher re-rupture rate compared with operative repair (12.6% vs. 3.5%). Laboratory studies show that after prolonged ankle immobilization in multiple species, structural organization is known to decrease. However, recent studies have suggested that the re-rupture rates can be lowered by reducing the period of cast immobilization and using early functional rehabilitation. Functional rehabilitation has proven to be more effective in reducing re-rupture rates than long-term cast immobilization.

Recovery from Achilles tendinopathy can take a year or more. No studies were found specifically comparing recovery times under different conservative management protocols – e.g.: with or without immobilization. However, the literature does have a lot to say about immobilization.

About immobilization

In this literature search, the single most common area of agreement among authors is the fact that immobilization leads to disuse atrophy and weakening of involved structures. The data became obvious in the 1980s when studies showed that loss of motion is designated as a primary cause of chronic pain and reinjury in Achilles management. Later we learned that immobilization results in a smaller quantity of scar tissue that is less able to resist higher loads. Reports show that skeletal muscle atrophy attributable to muscular inactivity has significant adverse functional consequences.
Several authors have come to the same conclusion that short-term voluntary immobilization is associated with atrophy and a diminished capacity of the muscle to develop maximal voluntary force. One of the most predictable consequences of cast immobilization is loss of muscle bulk.

What’s interesting is that the appearance of muscle atrophy masks the actual severity of loss of muscle strength. Chan discovered that with the use of a MAFO, the extent of atrophy of the leg muscles on MRI was significantly greater than expected from the clinical examination. Very significantly, data show that isometric muscle strength and muscle size declined following immobilization; however, change magnitude was greater for strength than for size. And strength loss happens much more quickly than previously thought. The strength of a maximal voluntary contraction is reduced by 24% after 2 weeks of immobilization. To make matters even worse, scarred portions may remain non-recoverably disorganized with associated inferior mechanical properties. It’s difficult to remember that the primary cause of injury in the first place was that the structure was too weak to handle the stress it was asked to handle. It’s no wonder, then, that evidence-based guidelines on the use of immobilization in the management of common acute soft-tissue injuries do not exist.

**Evolving conservative management protocols**

There is a definite trend away from immobilization and towards a more evidence-based approach to managing IAT. Basic science studies support the use of non-operative treatment and early active rehabilitation for Achilles tendon ruptures because complete rest and tendon unloading can be detrimental and prolong recovery. Indeed, previous work has shown that mechanical loading on tendons can induce tendon cell activation, the production of growth factors, tensional homeostasis, remodeling, and nuclear strain transfer. Fatigue testing also supports the concept that early activity leads to better recovery. Ultrasound analysis indicated increased matrix alignment (decreased collagen angle deviation) in the more active groups compared to the immobilized group. Along with early active rehabilitation, there is some biomechanical evidence to suggest that heel lifts can reduce the amount of tendon elongation (tensile strain) and compression (compressive strain) that occurs at the tendon insertion during daily activities that require ankle dorsiflexion.

Complete rest from all activities during the early phases of treatment may not be necessary. With a modified eccentric exercise protocol, pain has been shown to decrease from 5.4 at baseline to 3.0 at 3 months and 1.0 by 1 year. Early weight-bearing after Achilles injury has also been associated with decreased ankle stiffness compared to non-weight bearing protocols, which could lead to improvements in gait and function.

Exercise is the primary treatment strategy for all patients with IAT, yet the ideal parameters (type, dose, combination with additional treatments) of exercise are still unknown. Therefore, clinicians often recommend use of a heel lift, particularly during higher level activities. Exercise treatments that require end-range dorsiflexion may aggravate IAT symptoms. These data point to the need for a controlled motion environment to allow mobility and exercise for the foot-ankle complex for strengthening, but within set boundaries to avoid end-range motions for safety.
Importance of triplanar function

It’s interesting to note that calf/Achilles muscle activation occurs in the frontal (coronal) and not sagittal plane. At initial contact (first rocker), the calcaneus is driven from an inverted posture associated with supination during swing to an everted posture associated with pronation during stance. That frontal plane motion triggers a stretch-reflex mechanism to activate calf muscles to eccentrically decelerate the calcaneal eversion moment29. Therefore, the soleus and the medial gastrocnemius muscles are functional decelerators of calcaneal eversion and subsequent foot pronation due to the bias of their insertion into the medial aspect of the calcaneus29.

The posterior tibialis, through its insertion into the plantar anterior medial aspect of the calcaneus also serves to help decelerate calcaneal eversion at initial contact30. This frontal plane activation of these muscles occurs in spite of the fact that gravity and ground reaction forces are driving the ankle into plantarflexion at that time. Decelerating calcaneal eversion also helps decelerate internal or medial rotation of the tibia at initial contact29. Because it helps decelerate medial tibial rotation, the spiral alignment of the Achilles may have a very functional transverse plane purpose that should be considered when designing a conservative IAT management protocol.

An evidence-based approach to the conservative management of IAT

The happy medium between too much stress leading to injury, and not enough stress leading to weak structures getting even weaker, is the concept of controlled stress. Tendon development and healing is a well-orchestrated process requiring highly ordered molecular signaling events influenced by mechanical stimulation3. A successful non-operative healing strategy may ideally include active recovery and motion while simultaneously controlling motion to prevent tendon gap formation and subsequent lengthening22. The challenge is that the essential healing environment needed to restore tendon structure and function has yet to be defined22.

Traditional MAFOs reduce power crossing the ankle and therefore are not appropriate in the management of IAT. The human ankle produces a large burst of ‘push-off’ mechanical power late in the stance phase of walking, reduction of which leads to considerably poorer energy economy and the need for more positive work elsewhere to maintain walking speed31.

The newest generation of AFOs are made with carbon composite materials. As opposed to being designed simply to pick the foot up during swing, these carbon composite Energy Return AFOs (ERAFO) (Figure 2) return energy during gait to augment function of the ankle plantarflexor complex32,33,34. This reduces stress across the Achilles, facilitating normal functional ranges of motion while reducing end-range stress. An added benefit are data showing strengthening of the calf group in patients who were switched from a posterior leaf spring MAFO to an ERAFO35. In addition, the overall satisfaction of users is high, as the appearance is more modern and the function is superior to the existing orthoses33.
The ERAFO design should include an energy return spring-like footplate linked to an energy return lateral strut leading to a broad pretibial shell. The footplate should not immobilize the rearfoot in neutral but accommodate a foot orthotic device/wedge that can help keep the calcaneus functioning within normal ROM limits in the frontal plane. Graded levels of support are available in the prefabricated ERAFOs so the level of support can be matched to the functional needs of the patient. They range from more flexible for the athletic patient population to more supportive for the obese diabetic patients. The design protects against excessive dorsiflexion while facilitating the restoration of near-normal gait parameters. This could lead to an accelerated return to function while avoiding the effects of disuse atrophy. Simply stated, an injured Achilles tendon will heal faster when subjected to safe dynamic loading.

Summary

Medical evidence is clear that IAT is acquired when stress levels crossing the Achilles are beyond its capacity to manage that stress. Evidence is even more clear that immobilization makes weak structures even weaker and impairs and delays healing. The evidence-based environment in which healing can occur involves a foot orthotic/wedge in cases where there is excessive eversion of the calcaneus. Said foot orthotic is placed on the footplate of an ERAFO, and together that combination functions to relieve stress off of and to augment the power of the calf group while limiting disruptive end-range ROM. Early trials have been extremely positive in terms of pain relief, patient satisfaction and time to return to function. Outcome studies are needed to validate this concept.
